Introduction: Since 1990s numerous groups have been trying to develop a red blood cell analog due to the HIV epidemic of the time [1,2]. Even though some of these substitutes are now in phase III of clinical trials, their use is very limited due to side effects and short half life time within the human body [3]. As a result, there is still a need for an effective erythrocyte analog with minimum immunogenic and side effects, so that it can be used for multiple applications. Besides the imperative need of a blood substitute for in vivo use, there is also a need of it for in-vitro testing of medical devices and products. This study is focused on the synthesis and characterization of polyelectrolyte complex (PEC) chitosan-alginate microparticles. Physico-chemical and rheology properties of the PEC microparticles crosslinked with copper ions were studied to determine the set of parameters that would yield microspheres with deformable properties for applications in biomimesis of erythrocytes and drug delivery.

Methods: Crosslinked alginate microspheres were prepared by a modified water-in-oil (W/O) emulsion/gelation technique. The polymer used was alginate from Keltone (LV). Copper nitrate (Sigma) was used as the crosslinking agent. Sodium alginate was dissolved in dH₂O at a 3% (w/v) concentration and emulsified in an oil phase containing cyclohexane (Sigma) and Pluronic® L61 (kindly donated by BASF). A second aqueous solution containing 0.5M of the crosslinking agent was added to the emulsion under continuous stirring. After separation of the two phases, particles were collected by filtration through a 45-μm mesh.

Cu-alginate microparticles were coated using the layer-by-layer (LbL) absorption technique. The coating always started with the positive polymer and ended with the negative polymer. Microcapsules with zero, two, six, and ten alternating layers were fabricated. The cationic polymer used was a high-deacetylated, low-molecular-weight chitosan oligosaccharide lactate (Mw < 5000, 90% deacetylation) from Aldrich. Alginate was the anionic polymer used. After coating the particles, crosslinking ions were removed.

Surface morphology of the microparticles was examined with SEM after gold-palladium coating, and size distribution was determined with the Coulter LS13320 (from Beckman). To test particles’ deformability, the viscosity values of PEC particles were 5.90 mPa•s, which is not significantly different from the viscosity values of human blood (Figure 3). The highest level of toxicity was shown by uncoated Cu-crosslinked particles at 1000 μg/ml. The rest of the samples seemed not to affect cells at the conditions studied.

Conclusions: After removal of copper ions, multiple-layer microparticles presented deformability properties under micropipette aspiration. Particles suspended in simulated plasma presented viscosity values similar to blood’s values. Stability of particles after ion removal can be enhanced by multiple coatings. In addition, multiple coatings decreased toxicity of heavy-metal crosslinked particles.
